ABSTRACT

Glasses in the system \( xV_2O_5 \cdot 20Li_2O \cdot (80 - x) [0.6B_2O_3:0.42ZnO] \) (where \( 10 \leq x \leq 50 \)) have been prepared by a simple microwave method. Microwave synthesis of materials offers advantages of efficient transformation of energy throughout the volume in an effectively short time. Conductivity in these glasses was controlled by the concentration of transition metal ion (TMI). The dc conductivity follows Arrhenius law and the activation energies determined by regression analysis varies with the content of \( V_2O_5 \) in a non-linear fashion. This non-linearity is due to different conduction mechanisms operating in the investigated glasses. Impedance and electron paramagnetic resonance (EPR) spectroscopic studies were performed to elucidate the nature of conduction mechanism. Cole–cole plots of the investigated glasses consist of (i) single semicircle with a low frequency spur, (ii) two depressed semicircles and (iii) single semicircle without spur, which suggests the operation of two conduction mechanisms. EPR spectra reveal the existence of electronic conduction between aliovalent vanadium sites. Further, in highly modified (10V\(_2\)O\(_5\) mol\%) glasses Li\(^+\) ion migration dominates.

1. Introduction

The conductivity in glasses has been of interest for long time because of their potential technological applications. Use of glasses as electrolyte and electrode materials has given a boost to the study of ion transport in glasses and search for new glassy materials [1–5]. The mechanism of electrical conductivity in ion-electron conducting glasses is a challenging problem [5–8].

In recent years many glassy materials have been synthesized as binary or ternary systems using network forming oxides such as $B_2O_3$, $P_2O_5$, $TeO_2$ etc and alkali or silver oxides as modifiers by melt quenching method [1]. Microwave synthesis of materials is a new technology undergoing rapid developments due to potential advantages it offers such as reduced processing time, energy efficiency and products with enhanced properties. The only requirement of this method is that at least one of the components used for synthesizing materials should be a microwave susceptor [1,2].

Alkali borate glasses have been extensively studied over the past two decades to elucidate the nature and relative concentration of various borate units constituting the glass network [9]. $B^{3+}$ atoms in these glasses are both in trigonal and tetrahedral state. The concentration of these borate species in the glass structure is however determined by the nature and the content of the modifier oxide. In glasses containing $B_2O_3$ and $V_2O_5$, the coordination number and connectivities of both borate and vanadate species vary in a complex manner as a consequence of modification [9]. Further, modification is understood to be the reaction of oxide ion ($O^{2-}$), which results in structural changes, by creating non-bridging oxygens (NBOs). These NBOs constitutes anionic sites with different binding energies in comparison to those oxygens localized in boron tetrahedra [1]. Horopoulos et al. [10] pointed out that, the $Li^+$ transport in lithiated boron oxide glasses increases with $Li_2O$ concentration, not only due to $Li^+$ ion concentration but also due to structural modification. Ion conducting glasses with high $Li^+$/Na$^+$/Ag$^+$/Cu$^+$ concentration are called fast ion conductors (FIC) and they are promising glassy electrolyte for the solid state batteries [5,11,12].

Glasses containing transition metal oxide (TMO) such as $V_2O_5$, $Fe_2O_3$, $CuO$, $MoO_3$, $WO_3$, $CoO$, etc. are known to exhibit semiconducting property and hence these glasses have been studied extensively from the cathode point of view of batteries [1,13]. The existence of relative proportions of low and high valence states of transition metal ions (TMs) is responsible for the electronic conduction in these glasses [6,14]. It is expected that TMO added to alkali modified glass, results in mixed conduction [6,15,16].

EPR spectra of $V_2O_5$ containing glasses originate from $V^{4+}$-paramagnetic centers whose outer electronic structure $3p^5$, $3d^3$ enables unpaired magnetic moments of $3d^3$ electrons to interact with the electromagnetic field in the microwave range. Whereas, the electronic structure of $V^{5+}$ is $3p^6$, which has total electron spin zero. Since the $V^{4+}$ ion has electronic spin $s = 1/2$ and nuclear spin of $5/2$ is $l = 7/2$, one should expect interactions between corresponding magnetic moments resulting in the hyperfine structure [17]. Gupta et al. [18] pointed out that, long range electron spin–spin interactions between $V^{4+}$ ions and the spin–orbit coupling cause an anisotropy of the g-factor and the broadening of the individual lines. In glasses, only orientation averaged spectra can be observed, which can lead to additional reduction of hyperfine structure lines. It was seen in $V_2O_5$–$TeO_2$ glasses that the disappearance of hyperfine structure lines at higher contents of $V_2O_5$ is due to super-exchange interaction of $V^{4+}$–$O$–$V^{5+}$ chains [18]. In this study we used impedance and EPR spectroscopic studies to analyze conduction mechanisms in microwave synthesized $xV_2O_5$·$20Li_2O$·$(80 \text{ – } x) [0.6B_2O_3:0.4ZnO]$ glasses.

2. Experimental

Glasses were prepared by microwave heating technique using $xV_2O_5$·$20Li_2O$·$(80 \text{ – } x) [0.6B_2O_3:0.4ZnO]$ (where $10 < x < 50$) glass system. Analar grade vanadium pentoxide ($V_2O_5$) lithium carbonate ($Li_2CO_3$), orthobaric acid ($H_2BO_3$) and zinc oxide ($ZnO$) were used as starting materials. An appropriate quantity of weighed chemicals were mixed and thoroughly ground to homogenize the mixture and kept in a silica crucible inside a domestic microwave oven operating at 2.45 GHz and at a tunable power level up to a maximum of 850 W. When microwaves were switched on, complete decomposition of $H_2BO_3$ to $B_2O_3$, water and $Li_2CO_3$ to $Li_2O$, carbon dioxide was achieved in 2–3 min. Within 6–8 min of microwave exposure a good homogeneous melt was obtained, which was immediately quenched between brass blocks. The silica crucible was found to remain clean and unaffected during the short duration of melting. The glass was annealed in a muffle furnace for 1 h at 150°C to remove thermal strains that could have developed during quenching. The samples were in a sealed desiccator containing CaCl$_2$.

Glass transition temperature ($T_g$) of the samples was extracted from the thermograms recorded using Differential Scanning Colorimeter (Perkin Elmer DSC-2). For the electrical measurements, the annealed samples were thoroughly polished and coated with silver paste on both sides, which serve as electrodes having a thickness of about 0.1 cm and diameter of about 0.8 cm were used. The resistance of the sample was calculated by applying a dc field of 2 V and measuring the current through it using a digital electrometer (ECIL EA-5600). The conductivity of the sample was calculated using the relation:

$$\sigma_{dc} = \frac{d}{RA}$$

where $d$ is the thickness of the sample and $A$ is the area of the sample. Temperatures of the samples were measured using a chromel–aluclum thermocouple placed very close to the sample holder. The measurements were repeated with changed polarity of the applied voltages.

Capacitance ($C_{ph}$) and conductance ($G$) of the samples were measured as a function of frequency using a Hewlett-Packard HP 4192A impedance-gain phase analyzer from 100 Hz to 10 MHz in the temperature range 323–405 K. A home built cell assembly (having two terminal capacitor configuration and spring loaded silver electrodes) was used for the measurements. The temperature was controlled using Heating (Bangalore 560000, India) temperature controller with an accuracy of ±1 K in the entire range of measurements. The temperature of the sample was measured using Pt-Rh thermocouple positioned very close to the sample.

3. Results and discussion

The X-ray diffraction spectra of the annealed glasses did not show any sharp peaks (Fig. 1), indicating that the samples are
amorphous. The method used to extract glass transition temperature (\(T_g\)) and liquidus temperature (\(T_{\text{Liquid}}\)) is indicated in the DSC thermograms of heat capacity as shown in Fig. 2. Also, a thermogram of heat flow versus temperature of VBZ-1 glass is shown in Fig. 2 inset. Codes, composition, glass transition temperature (\(T_g\)), glass transition width (\(\Delta T_g\)), activation energy (\(E_{\text{ak}}\)), are listed in Table 1. The \(T_g\)s are decreasing with increasing \(V_2O_5\) mol%. This decrease in \(T_g\) can be explained on the basis of the structural changes occur due to network modification. A simple borovanadate network consists of a continuous random network formed by \(\text{VOO}_2\)^3 and \(\text{BO}_2\)^0 structural units. Boron is 3-connected and 3-coordinated, while vanadium is 3-connected but 4-coordinated. Therefore, the random network structure consists of \(B-O-B\) and \(B-O-V\) linkages in \(B_2O_3\) rich glasses while \(B-O-V\) and \(V-O-V\) linkages are present in \(V_2O_5\) rich glasses. Only \(B-O-V\) linkages are expected to be present when the concentrations of these two glass formers (\(B_2O_3\) and \(V_2O_5\)) are in equal proportion [19,20]. The variation of \(T_g\) with \(V_2O_5\) mol% can be rationalized on the basis of network connectivities, such that, as \(V_2O_5\) increases the stronger \(B-O-V\) and \(B-O-B\) linkages (bond dissociation energy of \(B-O\) is 715 kJ/mol) are replaced by \(V-O-V\) linkages (bond dissociation energy of \(V-O\) is 617.6 kJ/mol) [19]. Further, the glass transition width (\(\Delta T_g = T_{\text{Liquid}} - T_g\), where \(T_{\text{Liquid}}\) is the liquidus temperature and \(T_g\) is glass transition temperature) marginally decreases with increasing \(V_2O_5\) mol%. According to the empirical criterion proposed by Moinihan [21] the glass formers displaying widths \(\Delta T_g > 30\) are classified as “Strong” glass and those with \(\Delta T_g < 30\) are termed as fragile [22]. As can be seen from Table 1, \(\Delta T_g\) is much less than 30, hence the investigated glasses are “fragile”.

### 3.1. DC conductivity by four-probe method

The dc conductivity of the same composition from different batches prepared under identical conditions showed agreement within 5% error and dc conductivity on the same samples in different runs are within 2% error. Fig. 3 represents the variation of log (\(\sigma\)) as a function of inverse temperature for different \(V_2O_5\) concentrations. It is depicted from Fig. 3 that the conductivity values lie in the range 1.548 \times 10^{-9}-3.784 \times 10^{-6} S/cm when temperature varied from 313 to 423 K. Further, Fig. 3 shows that all the samples follow Arrhenius law:

\[
\sigma = \sigma_0 e^{-E_{ak}/kT}
\]

and the solid line represents the linear least square fits used to obtain the activation energies (\(E_{ak}\)) [23]. Fig. 4

shows the variation of log (\(\sigma\)) with \(V_2O_5\) concentration and Fig. 4 inset represents the variation of activation energy (\(E_{dc}\)) with \(V_2O_5\) concentration. As can be seen from Fig. 4, the variation is non-linear, indicating that different conducting mechanisms operating in the investigated glasses. Activation energy, \(E_{dc} = 0.83 \pm 0.002\) eV for \(x = 10\) mol\%, which is comparable with those of ion conducting glasses [24,25]. While for \(x = 30–50\) mol\%, \(E_{dc}\) is in the range 0.5 \(\pm 0.002\)–0.41 \(\pm 0.003\) eV. These values are comparable with the activation barriers of electronically conducting glasses [26]. Also, the non-linear variation of activation energy was reported by Garbarczyk et al. [8] and Jozwiak et al. [26] in their studies on silver–vanadate–phosphate and \(Li_2O–V_2O_5–P_2O_5\) glass system, respectively. In order to elucidate the observed variations in \(G_{dc}\) and \(E_{dc}\), impedance spectroscopy and EPR studies have been carried out.

3.2. Impedance spectroscopy

The impedance spectra of all the investigated glasses depend considerably on their chemical composition. The characteristic features of these spectra follow the nature of conduction mechanism. The experimental spectra (complex impedance representation) can be classified into three types: (i) single semicircle with a low frequency spur, (ii) spectra consisting of two depressed semicircles and (iii) single semicircle without spur [26]. The inclined straight line (spur) at the low frequency region could be the effect of mixed electrode and electrolyte interface. The magnitude of inclination in the straight line is related to the width of the relaxation time distribution [27]. The impedance spectra consisting of two semicircles represent mixed conduction while glasses exhibiting a single semicircle without spur are electronically conducting. Garbarczyk et al. [8] reported the simulated impedance spectra characteristic for ion conduction, mixed conduction and electronic conduction with the equivalent electrical circuits used to generate the spectra [8,28–30].

Conductance (\(G\)) and capacitance (\(C\)) were directly measured (for \(x = 10\) mol\%) from the impedance bridge and used to compute the real and imaginary parts of impedance using the relations given by Ross Macdonald [31]. Impedance plots of VBZ1 glass is shown in Fig. 5, which is used in dc conductivity determination. Values of \(Z^*\) (bulk resistance) corresponding to the intersection of low frequency side of the high frequency arc were used for the purpose. The dc conductivity was calculated using Eq. (1) and the values lie in the range of \(1.9 \times 10^{-7}–1.1 \times 10^{-5}\) S/cm (for \(x = 10\) mol\%). These values are comparable with those (measured using four-probe method) presented in Fig. 3. Impedance spectra of glass with \(x = 20\) mol\% showing two depressed semicircles, characteristic of mixed conduction are shown in Fig. 6. For \(x \geq 30\) mol\%, single semicircles without any spur are shown in Fig. 6 inset.

As can be seen from Fig. 4, isothermal conductivity at 313 K and activation energy (\(E_{dc}\)) varies nonlinearly with \(V_2O_5\) mol\%. This can be attributed to the enhanced interactions between polaron and mobile ions [29]. At lower \(x = 10\) mol\%, there is a reduction in the electronic component of conductivity due to the disruption of the glass network and the increased population of \(Li^+\) ions. Eventually, there is
an enhanced population of Li\(^+\) ions in the network structure compared to trapped polarons at \(x = 10\) mol\%. Thus, the ionic conductivity dominates. At \(x = 20\) mol\%, the interaction between electron and cation is maximum, suggesting a kind of transition from predominantly ‘ionic’ to ‘electronic’ conductivity. Hence, \(x = 20\) mol\% is considered to be the cross-over composition. In the present study, we identified two regimes viz. highly modified ‘ion’ conducting (\(x = 10\) mol\%) and least modified ‘electronically’ conducting regimes. As reported in the literature, alkali ion transport is characterized by high activation barrier [32]. Further, if electronic contribution to conductivity is significant as ionic contribution [1], then

\[
\sigma_{\text{total}} = \sigma_{\text{ionic}} + \sigma_{\text{electronic}}
\]

\[\log \sigma_{\text{total}} = \log(\sigma_{\text{ionic}} + \sigma_{\text{electronic}})\]  

\[\log \sigma_{\text{total}} = \log \left( \frac{\sigma_{\text{ionic}}}{1 + \frac{\sigma_{\text{electronic}}}{\sigma_{\text{ionic}}}} \right)\]  

\[\log \sigma_{\text{total}} \approx \log \sigma_0 - \frac{E_{\text{ionic}}}{kT} + \log \left( \frac{\sigma_{\text{electronic}}}{\sigma_{\text{ionic}}} \right)\]

the ratio \(\sigma_{\text{electronic}}/\sigma_{\text{ionic}}\) varies from glass to glass, since \(\text{Li}^+/(\text{V}^{4+} + \text{V}^{5+}) = \text{Li}^+/\nu_{\text{total}} = \nu_c\) varies.

This ratio plays a pivotal role in non-linear variation of conductivity. A similar trend is seen in glasses containing both alkali oxide and TMO’s [33–36]. The other possible explanation for the observed conductivity is that polaron percolation paths are blocked by alkali ions in alkali rich glasses [33–36]. More importantly modifier to network former ratio can be effective, it is a measure of disruption of the glass network. If the ratio is higher, the glass network becomes more depolymerized. In such a case the electron conduction paths are discontinuous [37]. In \(\text{V}_2\text{O}_5\) rich glasses conductivity increases while the activation energy decreases (see Fig. 4). This can be well explained using Austin–Mott’s relation [38]. Conductivity in such glasses is characterized by an electron transfer process represented by \(\text{V}^{4+} \rightarrow \text{O} \rightarrow \text{V}^{5+}\). The increase in \(\sigma_{dc}\) with \(\text{V}_2\text{O}_5\) concentration can be attributed to (i) a decrease in \(\text{V} \rightarrow \text{O} \rightarrow \text{V}\) distance resulting in a larger overlap of d-orbital wave functions and (ii) increase in the redox ratio, \(C = [\text{V}^{4+}]/([\text{V}^{4+}]+[\text{V}^{5+}])\). The dependence of conductivity on composition is clearly reflected in EPR study.

3.3. **EPR spectroscopy**

EPR spectra of the investigated glasses are shown in Fig. 7. As can be seen from Fig. 7, a strong absorption line arises from the fact that at high \(\text{V}_2\text{O}_5\) content, most of the vanadium ions are in the \(\text{V}^{4+}\) state. The absence of hyperfine structure (hfs) points to interaction between vanadium centers via \(\text{V}^{4+} \rightarrow \text{O} \rightarrow \text{V}^{5+}\) super-exchange mechanism. Generally, such glasses exhibit electronic conductivity [8]. However, the mechanism of conduction in glasses with high concentration of \(\text{V}_2\text{O}_5\) has been suggested as the transfer of an electron from \(\text{V}^{4+}\) site to a \(\text{V}^{5+}\) site. Structural groups formed in \(\text{V}_2\text{O}_5\) rich glasses, provide the path for the conduction of electrons [39]. The increase of the electronic conductivity in \(\text{V}_2\text{O}_5\) rich glasses can be explained by considering the decrease in the average distance between the TMI sites. According to Mott’s polaron theory, the dc conductivity rapidly varies with site spacing and redox ratio. The observed correlation between the concentration of \(\text{V}_2\text{O}_5\) and the appearance of hyperfine structure (hfs) can be justified, taking into account that two nearest aliovalent vanadium centers can exchange an electron via bridging oxygen. The least modified network is characterized by a strongly cross-linked network. In such a network, the conditions for electron hopping via \(\text{V}^{4+} \rightarrow \text{O} \rightarrow \text{V}^{5+}\) bonds are more favorable than highly disrupted network. An illustration of transfer of electron from \(\text{V}^{4+}\) site to neighboring \(\text{V}^{5+}\) site is shown in Fig. 7b. At \(x = 20\) mol\%, the EPR spectra consists of \(\text{V}^{4+}\) line with a weak but visible superimposed hfs, which indicates the cross-over from non-hfs regime to hfs regime. A similar cross-over point is seen at this composition in the dc conductivity studies. Further, in highly modified glasses (\(x = 10\) mol\%) ion (Li\(^+\)) transport dominates the polaron conduction.

4. **Conclusion**

Lithium–zinc–boro-vanadate glasses were synthesized by microwave method by varying \(\text{V}_2\text{O}_5\) concentration from 10 to 50 mol\%. Glasses were characterized by XRD and DSC studies. As the concentration of \(\text{V}_2\text{O}_5\) increases the \(T_g\) decreases suggesting that the rigidity of the network decreases while the fragility of glass itself increases. The dc conductivity study reveals a non-linear variation in conductivity and activation
energy. These nonlinearities are attributed to different conduction mechanisms due to the presence of both alkali oxide and TMO. Conductivity is predominantly ionic for glasses with low V_{2}O_{5} content while predominantly electronic for glasses containing higher content of V_{2}O_{5}. Conductivity transition occurs at the concentrations of alkali ion and TMI are nearly equal.
