ABSTRACT

The metal–matrix-nano-composites (MMNCs) in this study consist of a 6061 alloy matrix reinforced with 1.0 wt.% SiC nanoparticles that are dispersed within the matrix using an ultrasonic cavitation dispersion technique available in the Solidification Laboratory at the University of Alabama.

The required ultrasonic parameters to achieve (i) the required stirring and cavitation for suitable degassing and refining of the aluminum alloy and (ii) the adequate fluid flow characteristics for uniform dispersion of the nanoparticles into the 6061 matrix are being investigated in this study by using an in-house developed CFD ultrasonic cavitation model. The multiphase CFD model accounts for turbulent fluid flow, heat transfer, and the complex interaction between the molten alloy and nanoparticles by using the ANSYS’s Fluent DDPM.

The modeling parametric study includes the effects of the fluid flow, the ultrasonic probe location, nanoparticle size distribution, and initial location where the nanoparticles are released into the molten alloy. It was determined that the nanoparticles can be distributed quickly and uniformly into the molten 6061 alloy.

1. Introduction

Aluminum-based metal matrix composites (MMCs) have been extensively studied and widely used in the aerospace, automotive and military industries due to their high strength-to-weight ratios and enhanced mechanical and thermal properties including specific modulus, superior strength, stiffness, good wear resistance, fatigue resistance and improved thermal stability [1–3]. However, the particles commonly used are micron-sized which has a counterpart that the ductility of the MMCs deteriorates with high ceramic

The multiphase computational fluid dynamics (CFD) model accounts for turbulent fluid flow, heat transfer, and the complex interaction between the molten alloy and nanoparticles by using the ANSYS Fluent DDPM and $k - \omega$ turbulence model [14]. The CFD model is described in detail below.

2.1. **Fluid flow model**

In the Eulerian DDPM multiphase model an Eulerian treatment is used for each phase, and the discrete phase (nanoparticles) is designated as a granular phase. The volume fraction of the particulate phase is accounted for in the conservation equations.

The continuity equation for the phase $q$ is

$$\frac{\partial}{\partial t}(a_q \rho_q) + \nabla \cdot (a_q \rho_q \mathbf{u}_q) = \dot{m}_{pq} - \dot{m}_{ap}$$

(1)

The momentum balance for the phase $q$ yields

$$\frac{\partial}{\partial t}(a_q \rho_q \mathbf{u}_q) + \nabla \cdot (a_q \rho_q \mathbf{u}_q \mathbf{u}_q)$$

$$= -a_q \nabla P + \nabla \cdot \left[a_q \mu_q \left(\nabla \mathbf{u}_q + \nabla \mathbf{u}_q^T \right) \right] + a_q \rho_q g + F_{\text{DDPM}} + F_{\text{other}}$$

(2)

where $a_q$ is the phase volume fraction, $\rho_q$ is the density, $\mathbf{u}_q$ is the velocity, $\mu_q$ is the molecular viscosity, and $P$ is the pressure shared by all phases. $\dot{m}_{pq}$ characterizes the mass transfer from the $p$th to $q$th phase, and $\dot{m}_{ap}$ characterizes the mass transfer from phase $q$ to phase $p$. The momentum exchange term, $F_{\text{DDPM}}$, is considered only in the primary phase equations. The source term, $F_{\text{other}}$, includes the virtual mass force, lift force, turbulent dispersion force, etc.

Eqs. (1) and (2) do not solve for the velocity field and volume fraction of the discrete phase. Their values are obtained from the Lagrangian tracking solution.

2.2. **Particle tracking model**

The trajectory of a discrete phase particle is predicted by integrating the force balance on the particle. The force balance equates the particle inertia with the forces acting on the particle, and can be written as

$$\frac{d\mathbf{u}_p}{dt} = F_D + F_G + F_B + F_{\text{virtual-mass}}$$

$$+ F_{\text{pressure-gradient}} + F_{\text{lift}} + F_{\text{interaction}}$$

(3)

where $\mathbf{u}_p$ is the particle velocity, and all the terms at the right-hand are with a unit of force/unit particle mass.

The drag force, $F_D$, exerted on the particle by the viscous liquid tends to make it follow the fluid flow, and is calculated by

$$F_D = \frac{18 \mu}{\rho_p d_p^2} \frac{C_D Re}{24} (u - u_p)$$

(4)
where \( \mathbf{u} \) is the fluid phase velocity, \( \rho_\text{p} \) is the density of the particle, and \( d_p \) is the particle diameter. \( \text{Re} \) is the relative Reynolds number, which is defined as

\[
\text{Re} = \frac{\rho d_p |\mathbf{u} - \mathbf{u}_p|}{\mu}
\]

(5)

where \( \rho \) is the fluid density.

\( C_D \) is the drag coefficient which is calculated by the model of Wen and Yu:

\[
C_D = \frac{24}{\text{Re}} (1 + 0.15 \text{Re}^{0.68})
\]

(6)

The net effect of the buoyancy force, \( F_B \), and the gravitational force, \( F_G \), is

\[
F_G + F_B = \frac{g(\rho_\text{p} - \rho)}{\rho_p}
\]

(7)

The virtual mass force, \( F_{\text{virtual-mass}} \), is an unsteady force due to a change of the relative velocity of the particle submerged in the fluid, and can be calculated as

\[
F_{\text{virtual-mass}} = \frac{1}{2} \frac{\rho}{\rho_p} d \frac{d}{dt}(\mathbf{u} - \mathbf{u}_p)
\]

(8)

An additional force arises due to the pressure gradient in the fluid:

\[
F_{\text{pressure-gradient}} = \left( \frac{\rho}{\rho_p} \right) \mathbf{u}_p \nabla \mathbf{u}
\]

(9)

The Saffman’s lift force due to shear is generated by the local velocity gradients across the particle, and is calculated as

\[
F_{\text{lift}} = \frac{2KU_0}{\rho_\text{p}d_p} \frac{d_y}{|d_y|} (\mathbf{u} - \mathbf{u}_p)
\]

(10)

where \( K = 2.594 \) and \( d_y \) is the deformation tensor.

The term, \( F_{\text{interaction}} \), models the additional acceleration acting on a particle, resulting from interparticle interaction. It is computed from the stress tensor given by the Kinetic Theory of Granular Flows as

\[
F_{\text{interaction}} = -\frac{1}{\rho_p} \nabla \cdot \mathbf{T}_s
\]

(11)

where \( \mathbf{T}_s \) is the stress-strain tensor of the granular phase.

The chaotic effect of turbulence on the particle trajectories is accounted for using the stochastic tracking approach, i.e., the discrete random walk (DRW) model:

\[
\mathbf{u} = \bar{\mathbf{u}} + \xi \sqrt{\frac{2k}{3}}
\]

(12)

where \( \bar{\mathbf{u}} \) is the mean fluid velocity in the trajectory Eq. (3), \( \xi \) is a normally distributed random number, and \( k \) is the local turbulent kinetic energy.

\[
\text{Eq. (3)} \text{ can be cast into the following general form:}
\]

\[
\frac{d\mathbf{u}_p}{dt} = \frac{1}{\rho_p} (\mathbf{u} \cdot \mathbf{u}_p) + \mathbf{a}
\]

(13)

where the term \( \mathbf{a} \) includes accelerations due to other forces except drag force.

Integrating the transport Eq. (13) for the path of each particle yields

\[
\frac{dx_p}{dt} = \mathbf{u}
\]

(14)

where \( x_p \) is the particle position.

With Euler implicit discretization of Eq. (13), we get

\[
\mathbf{u}_p^{n+1} = \mathbf{u}_p^n + \frac{1}{1 + (\Delta t/\rho_p)} (\mathbf{a} + (\mathbf{u}_p^n/\rho_p))
\]

(15)

The new particle location is computed by a trapezoidal discretization of Eq. (14):

\[
x_p^{n+1} = x_p^n + \frac{1}{2} \Delta t (\mathbf{u}_p^n + \mathbf{u}_p^{n+1})
\]

(16)

2.3. Boundary conditions

The ultrasonic probe surface is set as velocity inlet, and the interface between liquid aluminum and air is pressure outlet. The other boundaries are set as wall. All of the Discrete Phase BC Types are set as reflect. The velocity inlet profile is defined in UDF, which is dependent on time as shown in Fig. 2.

2.4. Solution procedure

The SiC nanoparticles are injected at every fluid flow time step with a mass flow rate of 0.014 kg/s in the first second. The distribution of the particle diameters varying from 45 nm to 65 nm follows the Rosin–Rammler expression. Particles are tracked at every time step after the fluid velocity field is solved. Because of the low volume fraction of the discrete phase, one-way coupling is employed, which neglects the effect of the discrete phase on the fluid turbulence.
Fig. 3 – Fluid flow and particle distribution after 1s ((a) and (b)) and 3s ((c) and (d)).

3. Simulation results and discussion

Fig. 3 shows the fluid flow (colored by velocity magnitude (in m/s), similarly hereinafter) and particle distribution (colored by particle residence time (in seconds), similarly hereinafter) after 1s and 3s, respectively, when the injection is stopped. It can be seen from Fig. 3a and b that the flow is much stronger at the center of the furnace. Meanwhile, the particles are dispersed well from the bottom to the top, but more particles tend to stay near the wall. The fluid flow and particle distribution after 3s are shown in Fig. 3c and d. It is confirmed that the particles have little effect on the fluid flow because of the one-way coupling, as we can see that the flow field is almost the same as that after 1s. As time goes on after the injection is stopped, the uniformity of the particle distribution becomes even better. However, there are still fewer particles at the center where the flow is stronger, which indicates that the nanoparticles could not disperse well in strong flows. Additionally, the particle distribution stays almost the same henceforth. When the particles are injected from a different position which is about 15 mm beneath the probe, the distributions of the particles after 1s and 3s are shown in Fig. 4.
It is obvious that the particles are following the fluid flow. In the beginning, they are carried by the flow in the center to the bottom, and then back to the top near the wall. Nonetheless, after 3s when the distribution becomes stable, it has little difference with that when the particles are injected at the bottom, which demonstrates that the injection position will not affect the final distribution of the SiC nanoparticles.

**Fig. 4** - Particle distributions after 1s (a) and 3s (b) with a different injection location.

**Fig. 5** presents the fluid flow and particle distribution after 3s when the ultrasonic probe is placed at the bottom of the furnace. The flow pattern is changed due to the gravitational acceleration orientation, thus resulting in a different distribution of the particles. However, the general trend is basically the same, i.e., where the flow is stronger, there are fewer particles, and vice versa.

**Fig. 5** - Fluid flow and particle distribution after 3s with the ultrasonic probe placed at the bottom of the furnace (gravity vector up).
1. The particles are dispersed pretty well in the liquid pool except that there are fewer particles at the center of the furnace where the fluid flow is stronger.

2. The injection position will not affect the final distribution of the SiC nanoparticles as long as the flow is strong enough to disperse the particles, otherwise, the injection position will have a significant effect on the distribution of the particles.

3. When the ultrasonic probe is positioned at the bottom of the furnace, i.e., the gravity direction is changed, the nanoparticles have a different distribution due to a new flow pattern.

4. For the fluid flow, there is no doubt that the stronger the flow, the faster the particles are dispersed; however, the uniformity of the fluid flow (and not the intensity of the fluid flow) is crucial to the final distribution of the nanoparticles.

The effects of ultrasonic cavitation and acoustic energy attenuation as well as the furnace wall (lining) trapping of various type of nanoparticles will be determined in a future study.
